Answers 6 — Collocations
Version 1.0

1. Let's start by calculating the results for pair "valkoinen","talo" manually:

   - Frequency: Bigrams "valkoinen","talo" occurred 710 times.
   - Normalized frequence: Word "valkoinen" occurred 3665 times and "talo" 10 767 times. We get $\frac{710}{3665 \cdot 10767} \approx 1.8 \cdot 10^{-5}$.

   All the results for the frequency method are in Table 1 and for the normalized method in Table 2.

   We see that results are quite good even for as simple method as this.

2. For the collocation "valkoinen", "talo":

$$\begin{aligned} Mean(\text{"valkoinen","talo"}) &= \frac{-1 \cdot 710 - 2 \cdot 2 + 1 + 2 \cdot 6}{710 + 2 + 1 + 6} \\ &\approx -0.975 \end{aligned}$$

$$\begin{aligned} &Var(\text{"valkoinen","talo"}) \\ &= \frac{(-1-(-0.975))^2 \cdot 710 + (-2-(-0.975))^2 \cdot 2 + (1-(-0.975))^2 \cdot 1 + (2-(-0.975))^2 \cdot 6}{710 + 2 + 1 + 6} \\ &\approx 0.083 \end{aligned}$$

   Rest of the results, sorted by the variance, are in Table 3.

   This method has found in practice all the fixed collocations. However, results are not so good with sparse data: "vihainen mielenosoittaja" is definitely not a collocation.

   Size of the window surely affects the results. If it is too large, pairs start to occur together randomly too often, if too small, the collocations with longer effect are not found. If the second word of the collocation can be either before or after the first one, the method will clearly not work at all.

3. In statistical test, one should start by forming a null hypothesis. In our case, we assume that the words in a pair are independent: $P(s_1, s_2) = P(s_1)P(s_2)$. The tests will give a level of confidence for the null hypothesis. The significance level, below which the null hypothesis is discarded, is usually at most 0.05.

   In t-test we assume that the probabilities are normally distributed, and check if the expectation value for the observed data differs from the expectation value given by the null hypothesis. The t-values are given by

$$t = \frac{\hat{x} - \mu}{\sqrt{\frac{s^2}{N}}},$$

   where $\hat{x}$ is the sample mean, s^2 is the sample variance, N is the number of samples and μ is the mean of the distribution. In our case

$$\begin{aligned} \mu &= P(s_1)P(s_2) = \frac{C(s_1)}{N}\frac{C(s_2)}{N} \\ \hat{x} &= \frac{C(s_1, s_2)}{N} = \hat{p} \\ s^2 &= p(1-p) = \hat{p}(1-\hat{p}) \approx \hat{p} \end{aligned}$$

   For the pair "valkoinen talo" we get

$$t = \frac{\frac{710}{28181344} - \frac{2665 \cdot 10767}{28181344^2}}{\sqrt{\frac{710}{28181344^2}}} \approx 27.$$

If the t-value is over 6.314, the probability that the sample was from the distribution given by the independence assumption is less than 5%. Consequently, we can mark "valkoinen talo" as a collocation. Table 4 has values for all of the candidates. Note that the last pairs get negative values. This is because they occur together more rarely than the null hypothesis gives.

Table 4: *Results for the t-test*

χ^2-test is based on a simple assumption: We look at the separate probabilities and estimate how many times the words should occur together. This is compared to the observed co-occurrence value, and if they differ too much, the pair is likely to be a collocation.

Let's start by collecting the following table (table 5): These values can be used in the two-variable χ^2-test:

$$\chi^2 = \frac{N(O_{11}O_{22} - O_{12}O_{21})^2}{(O_{11} + O_{12})(O_{11} + O_{21})(O_{12} + O_{22})(O_{21} + O_{22})}$$

By assigning the numbers:

$$\begin{aligned} \chi^2 &= \frac{28181344(710 \cdot 28167622 - 10057 \cdot 2955)^2}{(710 + 10057)(710 + 2955)(10056 + 28167622)(2955 + 28167622)} \\ &\approx 358771 \end{aligned}$$

If the result for χ^2-test is over 3.843, the sample is drawn from an independent distribution with less than 5% probability. "Valkoinen talo" seems to be a collocation.

Table 5: *Quantities needed in the χ^2-test.*

	w_1=valkoinen	$w_1 \neq$ valkoinen
w_2 =talo	710 (valkoinen talo)	10767 − 710 = 10057 (punainen talo)
$w_2 \neq$talo	3665 − 710 = 2955 (valkoinen mopo)	28181344 − 710 − 10057 − 2955 = 28167622 (punainen mopo)

However, if we look at Table 6, we notice that almost every pair would be a collocation according to this. The reason is that the χ^2-test does not test for the pairs to be collocations, but whether they are independent. For example, the pair "ja", "olla" has a high correlation, but actually it is a negative one: They occur together less than they should according to the independence assumption.

4. Mutual information tells how much more information X gives for determining Y. If X and Y are independent, the mutual information is zero. For "valkoinen","talo",

$$\begin{aligned} I(x,y) &= \log_2 \frac{P(X,Y)}{P(X)P(Y)} \\ &= \log_2 \frac{\frac{710}{28181344}}{\frac{3665}{28181344}\frac{10767}{28181344}} \\ &\approx 9.0 \end{aligned}$$

The rest of the results are in Table 7.

The results seem to be good. The course book criticises that this method favours the less frequent words. Reason for this is the way that is used to estimate the probabilities, i.e. maximum likelihood estimation. Better result can be obtained if we instead set a prior for the words to be independent, and let the data modify it.

As a conclusion, we could say the following. The heuristic methods (ex. 1 and 2) are easy to apply and still give fair results. The statistical models applied in exercises 3 and 4 are justifiable as such, but they measure the correlation of the words, not whether they are collocations. However, if this is remembered, the results can be good. The statistical tests (ex. 3) may be harder to piece together, and the assumtions behind the methods must be kept in mind. In methods based directly on probability calculations (ex. 4), these assumptions are usually brought out more explicitly. In all methods based on probability estimates from data, one must choose how to approximate the probabilities. Maximum likelihood estimates can be too susceptible to sparse data. A better choice could be Maximum A Posterior (MAP) estimation with a prior belief that the words are independent.
